

The homophily survives every check that could have explained it away

Each mark is fig. 64's colonist/native result recomputed under one objection, against the middle of 2,000 relabellings of that same graph (grey).
Left: the three checks that share a statistic, drawn to one axis so they can be compared. Right: the same question with every body weighted equally rather than by its pair count, so no single large clique can carry the finding — a different statistic, hence a different scale. One objection moves the number: dropping the bodies whose printed name marks a community, which the coding reads as evidence, takes r from $+0.314$ to $+0.235$. A quarter of the effect is circular; the rest is not.
